FLIGHT: Clock Calibration and Context Recognition using Fluorescent Lighting

Zhenjiang Li, Member, IEEE, Wenwei Chen, Student Member, IEEE, Cheng Li, Student Member, IEEE, Mo Li, Member, IEEE, Xiang-Yang Li, Senior Member, IEEE, Yunhao Liu, Senior Member, IEEE

Abstract—In this paper, we propose a novel clock calibration approach called FLIGHT, which leverages the fact that the fluorescent light intensity changes with a stable period that equals half of the alternating current's. By tuning to the light emitted from indoor fluorescent lamps, FLIGHT can intelligently extract the light period information and achieve network wide time calibration by referring to such a common time reference. The light period can be also viewed as an indoor context indicator. As sampling the light sensor consumes substantially less energy, FLIGHT provides us a lightweight clock calibration and time synchronization solution. In addition, FLIGHT suits various mobility-enabled scenarios and it can work well even when the network is temporarily disconnected. We address a series of practical challenges and implement FLIGHT in TelosB motes. We conduct comprehensive experiments using a 12-node test-bed in both static and mobile environments. Over one-week measurement suggests that compared with existing technologies, FLIGHT can achieve tightly synchronized time with low energy consumption. We further leverage the periodical pattern and upgrade FLIGHT to recognize the ambient indoor/outdoor context, based on which the on/off states of a variety of location-based services can be controlled automatically for mobile devices.

Index Terms—Clock calibration, time synchronization, energy efficiency, fluorescent lighting, context recognition.

1 INTRODUCTION

In many distributed networking systems, retaining a common notion of time is one fundamental service and a variety of applications depend on its availability across network nodes. For example, in body area networks and healthcare monitoring networks [2]–[4], sensory data from multiple devices are usually processed to cooperatively analyze certain body movements or events of interest. Consistent time clocks among different devices are necessary for correct time alignment and data processing. The emerging High-speed Locational, Phone-to-Phone (HLPP) gaming [5] with a real-time requirement would benefit from such a service. A series of network-wide events must follow a strict common time order on different phones. Other typical application examples include sensor networks, mobile ad hoc networks, etc.

Maintaining common time in the network, however, faces substantial challenges. Due to the low-cost design, CMOS crystal oscillators serve as the most privileging signal source to generate on-board clocks. The frequency of an oscillator is not stable and it fluctuates with the surrounding environment, affected by various factors like temperature, humidity, voltage, pressure, etc. For example, the 32KHz oscillator adopted by popular sensor platforms has a clock drift rate of 30-50 ppm [6]. The clock drift in smart phones normally ranges from 5-100 ppm [7], [8]. Thus, clocks on different nodes need to be precisely calibrated for correcting above errors such that consistent time can be maintained. Due to the inherent uncertainty, no matter how accurately clocks are initially calibrated, they will ultimately tick towards divergency. Hence, frequent clock calibrations are necessary in most network systems. Existing networks may typically comprise hundreds or even more individual nodes, and those nodes are usually wireless interconnected in a multi-hop manner. As a direct consequence, frequently calibrating clocks prohibitively incurs high overhead and significant energy consumption for coordinating the entire network.

Great efforts have been made in the past decade to address above issues. Proposed solutions mainly rely on heavy intercommunications between nodes to exchange their local time references, including RBS [9], TPSN [10], FTSP [11], etc. The calibration error, however, gets accumulated hop by hop exponentially as the clock calibration spreads to the entire network [12]. In addition, those solutions lead to excessively high communication overhead and significant power drain in the system. Such facts largely prohibit the scalability of those solutions in practice. Against the problems, an emerging type of solutions have been recently proposed, which make use of certain external signal sources as common time references. Typical examples are using power lines [13], FM radio [14], radio stations [15], Wi-Fi [16]. Although such newly emerging solutions can dramatically reduce the communication cost, they also utilize radios for the clock calibration at the expense of higher power consumption. Even if clock calibration in [13]–[16] can
be performed less frequently, the energy consumption of each calibration could remain high. Besides, most of those solutions need specific hardware components to generate or capture periodical signals, which introduce extra cost and design complexity.

In this paper, we propose a new clock synchronization approach (and further extend to a context recognition approach) based on the following observations and facts. Alternating Current (AC) is a periodical signal with a frequency of 50 or 60 Hz. The AC frequency is adequately stable, i.e., $5 \cdot 10^{-5}$ stability measured by the Allan variance [13], [17]. In order for power delivered efficiently across the country, the phase difference between any two points remain highly constant [13], [17]. Powered by AC, the fluorescent light intensity thus changes with a stable period that equals half of AC’s. Commonly available in most indoor environments like universities, airports, hospitals, and supermarkets, the fluorescent light provides a universal period reference. Furthermore, the light sensor or camera is widely embedded in commodity wireless platforms, e.g., sensor nodes, and smart phones. This offers a great opportunity for a plenty of indoor applications to maintain common time by referring to the light emitted from fluorescent lamps.

The proposed solution has several key advantages. First, it does not require any extra hardware support. By sampling the light sensor with a sufficiently high rate, accurate period information can be detected for clock calibration. Hence, our solution is widely available on most existing commodity platforms. Second, taking advantage of the stability of the AC frequency, the detected light intensity, even from different lamps, exhibits a consistent and stable period, which ensures high synchronization accuracy. Third, compared with prior radio operation based solutions, sampling the light sensor consumes substantially less energy, which provides us a lightweight solution. Finally, since our approach is independent to the network message exchange, time synchronization can be retained even when the network is temporarily disconnected. When individual devices are moving, they can still obtain desired periodical patterns for clock calibration. Such characteristics particularly suit various mobility-enabled scenarios.

In addition to its wide availability, the periodical pattern of fluorescent lighting is also a unique feature in indoor environments and can be treated as a context fingerprint. With such an observation, the possibility to intelligently distinguish the indoor environment from the outdoor environments is further explored. The recognition is beneficial for mobile devices, based on which the on/off states of a variety of location-based services can be controlled automatically, e.g., GPS is turned on only when the device is detected to be outdoor.

Successfully implementing our idea is non-trivial. We first empirically study the feasibility of detecting periods from the fluorescent lighting. Starting from static deployment in the laboratory, our measurements validate that the fluorescent lighting is able to serve as a viable reference for time calibration. We then propose the Fluorescent LIGHTing (FLIGHT) approach for achieving a low-power and accurate clock calibration. FLIGHT can intelligently extract the period information from the fluorescent light in both static and dynamic environments. In addition, to achieve a lightweight FLIGHT implementation, we address a sequence of practical issues including responsive light sensor sampling, period detection with interference from other light sources, etc. To evaluate our design, we implement FLIGHT in TelosB motes and conduct extensive experiments using a 12-node test-bed in the laboratory and further with mobility across the university main academic building of over 20,000m$^2$. The results demonstrate that FLIGHT can achieve tightly synchronized time with low energy consumption. On the other hand, for the context recognition, we leverage the periodical pattern and the intensity of fluorescent lighting. A lightweight solution is achieved for a variety of embedded devices. We validate the design from 200 different sites in our campus. The results show that our solution can approach up to 95% detection accuracy.

The rest of this paper is organized as follows: In Section 2, we introduce the preliminary information and perform a measurement study. The architecture and the design detail of FLIGHT are given in Sections 3 and 4, respectively. In Section 5, we evaluate FLIGHT’s performance through extensive experiments. The context recognition design is introduced in Section 6. Related works are reviewed in Section 7 and we conclude this paper in Section 8.

## 2 Preliminary

In this section, we first discuss the clock calibration problem that this paper studies and compare it with the traditional clock synchronization problem. We then detail the target applications for clock calibration and context recognition. We illustrate the principle of fluorescent lighting and present our initial empirical measurement study that motivates this work.

### 2.1 Clock calibration v.s. synchronization

A native clock is the clock driven by a node’s built-in crystal oscillator directly. We denote the native clock as $c_n(t_0 + t)$, referring to the measured time duration from an initial time $t_0$ until $t$ by the native clock. Without loss of generality, we assume $t_0$ to be zero; hence the native clock can be written as $c_n(t)$ for short. The periodical pattern of the fluorescent light intensity can be treated as a global reference clock, which is denoted as $c_l(t)$. In our system, the AC frequency is 50 Hz; thus, the frequency of the global reference clock $f_g$ is 100 Hz and the time unit of the global reference clock is $1/(100Hz) = 10ms$.

In addition, each node maintains a logic clock, written as $c_l(t)$. The logic clock is used by upper-layer applications and it advances as follows:

$$c_l(t) = c_l(0) + \int_0^t r(\tau)d\tau,$$  
(1)
where \( r(\tau) \) is the instant rate of the native clock at time \( \tau \). The goal of FLIGHT is to ensure logic clocks consistent among different nodes.

Clock synchronization in prior literatures [9]–[11] ensures the absolute clock values of different nodes to be consistent, while in this work we primarily focus on clock calibration, which mainly ensures that different clocks advance with a same speed. Referring to Eq. (1), clock synchronization essentially first compensates the difference of the starting time \( c_{i}(0) \) of each node and further maintains consistent clock ticks for \( \int_{0}^{r(t)} dr \). On the contrary, clock calibration only guarantees a consistent clock rate for \( \int_{0}^{r(t)} dr \) despite of different node starting times. Therefore, with accurate clock calibration, clock synchronization can be easily achieved by compensating the initial time differences of nodes, while sole clock calibration already suffices to support many practical applications. In this paper, we first propose FLIGHT to achieve an accurate clock calibration, and then we discuss how FLIGHT can be integrated with existing mechanisms (e.g., FTSP [11]) to achieve precise clock synchronization with much reduced communication and energy overhead.

2.2 Target applications

The primary applications of FLIGHT are those, in which a precise timing service across indoor environments is desired with minimal communications. For instance, body area networks and healthcare monitoring networks need to detect and report a series of gestures, movements, and accidents (e.g., falling down). Clock calibration could be adopted in such applications since event detections rely on an accurate data timing sequence. Absolute time values of sensory data, however, are not necessarily needed. In such a scenario, nodes are attached to human bodies. The miniature requirement on the node size prevents prior external signal based approaches, e.g., [13]–[15], from being applied due to the extra hardware requirement. On the other hand, the node density in such applications could be high. Frequent message exchanges of radio-based approaches, like [9]–[11], can influence the regular event detection and report. Against such issues, body area and healthcare monitoring networks would greatly benefit from the design of FLIGHT.

In wireless sensor networks, clock calibration can support many services as well, like the target tracking, the topology control, and the event logging for diagnosis where the order of events rather than their precise time matters. Sensor networks normally consist of hundreds, or even thousands of nodes. Extra hardware components [13]–[15] may dramatically increase the deployment and maintenance costs. On the other hand, the useable bandwidth resources of sensor nodes are usually limited (e.g., due to low data rates and duty-cycled operation mode). FLIGHT is parallel to the wireless communication, which saves bandwidth and simplifies the MAC design.

A variety of location-based services for mobile devices can benefit from the extended design from FLIGHT for the context recognition. We can avoid launching services improperly to save energy and guarantee their performance. For instance, before turning on GPS, one may first check whether it is outside a building. Before searching for the access points of WiFi, one may check whether it is inside or near buildings. Due to the requirements on expensive sensors, solutions like [18] may not be applicable for low-end smart phones and embedded devices, e.g., on-board GPS module, embedded computer system, mobile sensor motes. The solution proposed in this paper, however, can overcome the hardware barrier and achieve a lightweight context recognition efficiently.

There is no strict requirement on the space and time coverage of fluorescent lamps in our design. As we will show later, the period information can be extracted even when the detected light intensity is very low. One fluorescent lamp, thus, can coordinate plenty of surrounding nodes. Fluorescent lighting from different lamps can exhibit a stable and consistent period. Hence, lamps can be sparingly used in the field. In our experiment, only a small number of lamps can coordinate all the nodes in our laboratory of 600m². Lamps can also coordinate nodes in different rooms or even different buildings.

2.3 Principle of fluorescent lighting

The fluorescent lamp is a gas discharge lamp using electricity to excite mercury vapor. When the lamp is turned on, the electric power heats up the cathode to emit electrons. Electrons quickly jump from a higher energy level to a lower level and photons will be emitted. Emitted photons are absorbed by electrons in the atoms of the interior fluorescent coating of lamp, leading to physical reactions with emission of visible light. After being heated up, the gas conductivity inside the lamp rapidly rises, allowing the alternating current to flow through and continuously emit light. From the principle of fluorescent lighting, the emitted light is expected to exhibit a periodical pattern since its AC power source is a periodical signal. As the period of AC is adequately stable and phase-coherent, we expect that the light generated by fluorescent lamps can be used as a periodic reference for clock calibration.

2.4 Empirical measurement study

We focus on evaluating following two properties of the fluorescent lighting strategy: stability and accuracy of detected light periods. In the rest of this paper, we mainly take standard TelosB motes as a vehicle to present the measurement results and the design principle. Due to the limited computation capacity and buffer size, design challenges of FLIGHT for TelosB motes are more general. Dealing with the performance optimization in other high-end devices, like smart phones and laptops, can further serve as a promising future work of this paper. In the experiments, 12 TelosB motes are deployed
in the laboratory and the longest distance between any
two pairs of sensor nodes is up to 15m. We report
the results based on one week measurement. Among those
12 deployed TelosB nodes, the minimum distance to a
light lamp is around 20cm and the maximum distance is
about 7m. The detected light intensity is measured by
the voltage value of two pins of the light sensor.

Fig. 1. Single-lamp experiment in the laboratory

We start from examining a simple case, in which
only one lamp is open. As a benchmark, we plot the instant
voltage value from two front-end pins of the light sensor
using an oscilloscope. Through one week measurement,
we observe that the reading from oscilloscope is quite
stable and exhibits a regular fluctuation with a period of
10ms (depicted in Figure 1(a)), which is equivalent
to 100Hz. In practice, sensor nodes need to sample
the light sensors. After sampling, we see that the sampling
results exhibit the same periodical property as depicted
in Figure 1(b), which suggests that the obtained light
intensity pattern can be used for clock calibration. Figure
1(c) summarizes the statistics of the detected period
lengths. We report the
trace, the error is smaller than 65μs for most cases.

In summary, our initial empirical studies validate the
stability and accuracy of fluorescent lighting in practice.
Later we will make use of such lighting period information
for clock calibration in FLIGHT.

3 SYSTEM OVERVIEW

In this section, we first introduce the basic idea of the
fluorescent lighting based clock calibration scheme. We
then give an overview of the design challenges as well
as the FLIGHT architecture and implementation.

3.1 Principle of clock calibration

The objective of FLIGHT is to ensure logic clocks consist-
tent among different nodes. In Section 2.1, Eq. (1) has
stated that the logic clock evolves as
\[ c_l(t) = c_l(0) + \int_0^t r(\tau) d\tau, \]
where \( r(\tau) \) is the instantaneous rate of the native
clock at time \( \tau \). Ideally, we have \( \int_0^t r(\tau) d\tau = c_n(t)/f_n \)
where \( f_n \) represents the claimed freency of the built-
in crystal oscillator. In practice, however, \( f_n \) is not stable
and it fluctuates due to the variances of surrounding
environmental parameters as mentioned in Section 1. In
other words, \( f_n \) is not constant in real systems and keeps
varying. Such uncertainty is also known as skew [7],
[19]. We utilize \( f_n(t) \) to capture the time-varying nature of
\( f_n \). By defining the \textbf{frequency ratio} as
\( \alpha(t) = f_n(t)/\overline{f} \),
Eq. (1) can be rephrased as follows:
\[ c_l(t) = c_l(0) + c_n(t)/(t \int_0^t (\alpha(\tau) \cdot f_g) d\tau), \]
where \( \overline{\alpha}(t) \) is the average value of \( \alpha(t) \) from time 0
to \( t \). As unveiled in existing works [7], [12], [19], clock
skew can accumulate with time. Thus, FLIGHT should
calibrate clocks to minimize its negative impact by con-
trolling the differences of each \( c_n(t)/(\overline{\alpha}(t) \cdot f_g) \) among
different nodes; otherwise, logic times will rapidly ex-
hibit heterogeneous advancing rates respect to the global
reference and among themselves. As a convention, the
time difference caused by the skew accumulation is also referred to as drift.

Eq. (2) essentially indicates that by continuously estimating the frequency ratio, the logic time can be precisely maintained. As a matter of fact, the variance of the logic time is limited within a short period of time and most applications can tolerate certain amount of such errors [20], [21]. Hence, instead of continuously measuring the frequency ratio, we predict the logic time by using the native clock and the estimated frequency ratio. To further guarantee the accuracy of such a prediction, we configure the clock calibration in a periodical fashion, as depicted in Figure 3.

3.2 System architecture and implementation

Figure 4 depicts the system architecture. There exist three major components in FLIGHT: clock calibration, logic time interface, and interval adaptation. Based on the readings from the light sensor, the period generation module in the calibration component is launched to produce the global reference clock for later calibration. The output of the period generation module acts as the input of the logic time maintenance module, which is responsible for updating the frequency ratio \( \alpha(t) \) and correcting the accumulated drift between two calibrations. The newly obtained logic time can be used by upper layer applications. Meanwhile, the output from the logic time maintenance module can be adopted to determine the interval length for the next calibration.

We implement FLIGHT in TinyOS 2.1x on the TelosB platform. The native clock is driven by the built-in crystal oscillator with a 32KHz frequency. The AC frequency in our experiments is 50Hz. Thus, the frequency of the global reference clock is 100Hz. The kernel of FLIGHT includes 600 lines of NesC code that was compiled to 2242 bytes of RAM and 16114 bytes of ROM. As a result, FLIGHT only occupies 23% of the total buffer and the remaining space is available for other applications.

We use the built-in light sensor on the TelosB mote in our experiments. The light sensor utilizes an ADC module to measure the light intensity and records it as a corresponding voltage value in the register. The standard TinyOS packages the ADC module and relies on the MSP430 Timer to control the ADC sampling. The maximum sampling rate limited by TinyOS is around 1KHz, which is not fast enough for FLIGHT. To overcome this issue, we write a driver to directly access the register of the ADC module. By doing so, the effective sampling rate can break the 1KHz barrier and achieves up to 83KHz in the implementation. There are some system parameters that we have not touched yet and we will later discuss each of them in corresponding sections.

4 System Design

4.1 Period generation

After sampling the light sensor, nodes need to extract the light period and further generate a series of signals with the same period to serve as the common time reference. In this subsection, we discuss how to efficiently and precisely generate such global reference signals.

4.1.1 Challenging issues

Assume the light sampling rate to be 10KHz. Ideally, 100 = 10ms × 10KHz samples are detected within one light period. A greedy searching solution for counting the maximum (or minimum) points cannot work here, since there exist multiple local maximum points in one light period for the general multi-lamp scenario. A more sophisticated method may record samples of one period and then apply the greedy searching. When one local maximum point is detected, if its value is close to the recorded maximal value, such a point can be viewed as a period delimiter. Nevertheless, as we will show next in the mobile case, although the light period is still stable, the detected light intensity can fluctuate significantly.

We perform experiments to verify such a point in the mobile environment. In the experiments, three persons roam in the main academic building of an University and each of them holds one TelosB mote and one laptop computer. Due to the limited buffer size, motes are connected to computers through a USB 2.0 port for storing sampled data. Particularly, they move cross different floors. During the movement, sensor nodes might be rotated, shaken, or even temporarily blocked (not sight-in-line to lamps). The moving duration of each person lasts around 120 minutes. During the movement, many places that we passed by are only sparsely covered by lamps, i.e., some places are fully covered by the light while some places are relatively dark. To clearly present our harvested trace, we depict one representative clip in Figure 5(a), which contains the portions collected in both
light and dark places. From the zoom in sub-figures in Figure 5(a), however, we can observe that the detected pattern always demonstrates a good periodical property in both light and dark scenarios. The only difference is the observed light intensity.

To further exploit the sensitivity of the detected light intensity, we record the detected pattern of one node when it is rotated. We hold the sensor node in the multi-lamp laboratory and its distance to the closest lamp is around 4m. Initially, the light sensor faces to the lamp. After a 180-degree rotation, the light sensor almost faces to the ground and the incident light is mainly the scattering light. Figure 5(b) summarizes the result during a 540-degree rotation. In the zoom in sub-figure, we can see that even when the light sensor is opposite to the lamp and the detected light intensity is low, the detected pattern can exhibit a periodical property as well. As we will show later, one lamp can cover up to around 100m² floor size such that fluorescent lamps can be sparingly used in FLIGHT. Now the question is how we can capture such period information under such intense light fluctuation.

One possible way for the period generation is to use existing DSP techniques, e.g., self-correlation. In principle, they are effective for extracting periodic signals in both static and mobile environments. In practice, however, the extensive computation burdens involved in those techniques will occupy the MCU of nodes for a long time, which may disturb the processing of other important tasks, and inevitably consume more energy.

4.1.2 Filtering solution

To tackle such challenges, we propose to utilize a lightweight filtering method to extract periods. In Figure 6, we perform the Fast Fourier Transformation (FFT) for the trace depicted in Figure 5(a) and find that the trace demonstrates a dominant frequency response around 100Hz. Such a result indicates that the light intensity indeed changes with a stable period of 10ms. However, due to noises, the light samples are also mixed with other frequency band components. Figure 6 implies if the trace is processed by a low-pass filter with a cutoff frequency between 135Hz and 175Hz, the trace can be used to generate stable periodical signals.

Denote $x[i]$ to be input function and $y[i]$ to be the output function, where $i$ is the sample index. In general, the first-order filter can be expressed as:

$$ y[i] = a \cdot x[i] + b \cdot y[i-1], $$

where $a$ and $b$ are filter parameters and $a + b = 1$. Based on Eq. (3), a higher order filter can be further constructed. For instance, the second-order filter is $y[i] = a \cdot x[i] + b \cdot (a \cdot x[i-1] + b \cdot y[i-2])$. A general expression for any $m$-order filter, where $m \geq 1$, can be obtained iteratively. The settings of $a$ and $b$ have been discussed in Appendix. We conduct an experiment to evaluate performances of the period extraction with filters of different orders. The result shows that if the filter order is small, the trace still exhibits multiple maximum points. When the filter order is sufficiently high, it becomes viable to apply a simple greedy searching scheme to accurately extract periods. In our experiments, we find that a 6-order filter is adequate in FLIGHT. In such a case, a node only needs to buffer 6 latest samples for the filtering operation. The involved computation burden contains merely 12 multiply operations, 6 plus operations and the greedy searching, which is particularly beneficial for resource constrained mobile devices.

In Figure 7, we summarize the detection accuracy of the filtering method. We have shown the detection errors in static scenarios in Section 2. For the mobile scenario in Figure 5(a), Figure 7 shows that the error is bounded by 165µs and smaller than 100µs most of the time. The detection errors in our rotation experiments are also within 165µs and less than 65µs for majority cases.

4.2 Logic time maintenance

To maintain the logic time, frequency ratio must be updated by the extracted light period in each calibration.

4.2.1 Frequency ratio calibration

According to the output from the period generation component, the generated signal can be viewed as a
common time reference. Suppose the start time of the calibration and the calibration window size are \( t_c \) and \( \tau \), respectively. For the presentation simplicity, we assume \( t_c = 0 \) without loss of generality. The basic principle of clock calibration is illustrated in Figure 8. In Figure 8, there are totally \( M \) samples between the first and the last generated periods. Each \( I_j \) represents the sample index where \( 1 \leq j \leq M \). We denote the native clock frequency in \( \tau \) as \( f_n(\tau) \). Based on the generated global reference, \( \bar{f}_n(\tau) \) can be measured by \( f_n(\tau) \) as follows:

\[
\frac{L}{f_g} = \frac{I_M - I_1}{f_n(\tau)}, \tag{4}
\]

where \( L \) is the number of light periods detected in the calibration window \( \tau \). Based on the definition, the frequency ratio can be calibrated by the following equation:

\[
\hat{\alpha}(\tau) = \frac{\bar{f}_n(\tau)}{f_g} = \frac{I_M - I_1}{L}. \tag{5}
\]

The rationale behind the calibration is that native clocks of different nodes run with different speeds. By referring to the global reference, frequency ratios are calculated to compensate those differences. If the measured native clock \( f_n(\tau) \) in Eq. (4) is accurate, the frequency ratio in Eq. (5) can precisely capture the real situation when predicting the logic time after the calibration.

### 4.2.2 Calibration window configuration

In Figure 8, \( M \) native clock ticks have been elapsed during the calibration window \( \tau \). Due to the instability of the native clock, \( M/f_n \) may not exactly equal to \( M/\bar{f}_n(\tau) \), where \( f_n \) is the claimed clock frequency and \( \bar{f}_n(\tau) \) is the average value of the native clock within \( \tau \). We denote this offset in the calibration window as \( o(\tau) = M/\bar{f}_n(\tau) - M/f_n \) and it can be viewed as a relative drift of the native clock with respect to the global reference since both \( f_n \) and \( f_g \) are constant. The relative skew, thus, can be expressed as \( s(\tau) = o(\tau)/\tau \).

On the other hand, due to jitters, each sampling point (except the first one \( I_1 \)) we artificially fix it and view it as the starting point) actually further exhibits a tiny shift, \( h \), compared with the ideally stable sampling point. Prior studies have shown that such a shift follows \( h \sim \mathcal{N}(0, \sigma_h^2) \). Therefore, the really observed offset in the calibration window \( \tau \) can be expressed as:

\[
\hat{o}(\tau) = \sum_{j=2}^{M} \left[ \left( \frac{I_j}{\bar{f}_n(\tau)} + h_j \right) - \left( \frac{I_{j-1}}{\bar{f}_n(\tau)} + h_{j-1} \right) \right] - \frac{L}{f_g},
\]

\[
= o(\tau) + h_M, \tag{6}
\]

where each \( h_j \) indicates the shift for the sampling point \( I_j \) for \( 2 \leq j \leq M \). In Appendix, we can show that if \( \hat{o}(\tau) = o(\tau)/\tau \) is an accurate estimation of \( s(\tau) \), \( f_n(\tau) \) will precisely estimate its true value \( \bar{f}_n(\tau) \). In other words, the frequency ratio \( \bar{f}(\tau) \) can be well measured by the observed frequency ratio \( \hat{\alpha}(\tau) \) in Eq. (5), yielding a good calibration result. We utilize \( \text{Var}[\hat{s}(\tau) - s(\tau)] \) to quantify the estimation accuracy. By skew’s definition, we have:

\[
\text{Var}[\hat{s}(\tau) - s(\tau)] = \text{Var}[\frac{(\hat{o}(\tau) - o(\tau))}{\tau}] = \sigma_h^2/\tau^2. \tag{7}
\]

Eq. (7) suggests that it is beneficial to set the calibration window to be large. However, we argue that in practice, the solution is beyond such a simple strategy and there exist practical limitations. For example, the buffer size limitation may prohibit to obtain enough data during the calibration. Devices usually have buffers with limited capacity for multiple applications, which may not be able to hold enough samples during the calibration window. For instance, the buffer size of a TelosB mote is \( 10kB \), in which \( 8kB \) can be allocated to store sampled data at the most. If each sample occupies two bytes, the buffer can hold up to \( 4k \) samples. If the sampling rate is \( 10kHZ \), only \( 40 \) periods can be collected, which may not be enough for an accurate calibration.

To tackle such an issue in FLIGHT, we propose to parallel the sampling and period generation operations. After initial raw data have been filtered, we can drop those data and only store 1) the number of periods that have been detected, and 2) the total amount of samples within those periods. By doing so, the buffer size is virtually increased so as to accommodate adequate data for the calibration. On the other hand, the real buffer occupancy is small and it will not conflict with other applications. To implement such an idea in FLIGHT, we insert the computation process of filtering between the interval of two consecutive samplings. Whenever a new sample has been obtained, it will be processed immediately. We claim that the selection of the sampling rate and the order of the filter should guarantee that the filtering computation must be completed in between two consecutive samplings; otherwise, the data loss will lead to errors in the generated global reference signals. In Section 5, we will verify such a statement.

### 4.2.3 Logic time updating

After the frequency ratio has been updated as \( \hat{\alpha}(\tau) \), the logic time afterward can be predicted by using such a new frequency ratio and the native clock till the next calibration window. To maintain an accurate logic time, in addition to the calibration, we also need to correct the drift accumulated between two consecutive calibrations. We utilize Figure 9 to illustrate such a point. In the first calibration interval, we set the logic time to \( 10,000\mu s \) at the end of the last detected period. Since
the period length of light is 10 ms = 10,000 μs, the logic
time should increase 10,000 μs whenever one period has
elapsed. After the first calibration, we assume that after
10 light periods, the node performs the next calibration.
If the clock is stable, the logic time at the last detected
period in the second calibration should be 130,000 μs.
However, the real logic time might be 130,200 μs due to
the clock uncertainty. Such an error cannot be corrected
by the frequency ratio updating, while it will naturally
deteriorate the time consistency among different nodes.

The insight obtained from Figure 9 is that if the
accumulated error can be controlled within a certain
range, the last several digits contains the information
about the drift. In Figure 9, if the accumulated drift is
smaller than 10,000 μs, in principle, the logic time
can be corrected by resetting the last four digits to
zero, i.e., 130,200 μs will be changed to 130,000 μs. If
we denote \( t_{c_i} \), \( L_i \), and \( n_i \) to be the finish time of the
ith calibration, the number of light periods detected
in the ith calibration, and the number of light periods
between the ith and \( i + 1 \)th calibration respectively, we
can essentially adjust the logic time at the last detected
period to \( c_i(t_{i+1}) = c_i(t_i) + (n_i + L_i)/f_g \) to eliminate
the drift. Now we formally derive the logic time in FLIGHT.
If \( t = t_{c_i} \), then

\[
    c_i(t) = \sum_{j=1}^{i} (L_j + n_j)/f_g. \tag{8}
\]

In fact, each \( n_j \) is unknown. The operation in Eq. (8)
can be achieved by resetting the last several digits of the
logic time to zero (the exact digit number is related to the
required error bound), or \( n_j \) is estimated by \( \alpha(t_{c_{j-1}}) \times
n_{j-1} \). On the other hand, if \( t_{c_i} < t < t_{c_{i+1}} \), we have:

\[
    c_i(t) = c_i(t_{c_i}) + (c_{i}(t) - c_{i}(t_{c_i}))/\left(\alpha(t_{c_i}) \cdot f_g\right). \tag{9}
\]

Now, by directly tuning to the light period at the end
of each calibration, the logic time can be precisely aligned
to the global reference and the drift accumulated
in the previous calibration interval is thus eliminated.

### 4.3 Calibration intervals

In this section, we describe how we can further utilize
the calibration interval to reduce the number of samplings. We also discuss how to determine the interval length between two calibrations.

In Figure 9, if a proper calibration window size should
at least contain 13 light periods, a naive method is to
extract 13 light periods for each calibration window.
However, Figure 9 implies that if we know that 10 light
periods will elapse between two consecutive calibration
windows, we only need to sample three additional peri-
ods in the second calibration window (Calibration 2).
By using the similar method in Eq. (8), the node can estimate
how many light periods have been elapsed between
Calibrations 1 and 2. In addition to the number of the
light periods between the light periods detected in Calibration 2, the total
number of light periods between two calibration win-
dows can be obtained. On the other hand, the number
of the native clock ticks are always recorded (to calculate
any instant logic time). As a result, the frequency ratio
can still be calibrated using Eq. (5). Benefited from
such a method, although only three light periods have
been extracted in Calibration 2, the frequency ratio can
be accurately calibrated based on 13 light periods. In
practice, the calibration interval normally spans more
than 20 minutes. Hence, nodes are able to sample a small
number of periods while still achieve high accuracy in
each calibration.

In Section 5, we examine the calibration interval selection
to balance the calibration accuracy and cost. In this
study, we also propose a dynamic interval adjustment
scheme. We introduce a drift controlling factor \( u \) to
restrict the total amount of logic time errors accumulated
between two calibrations. Suppose the drift detected
at the last period in the ith calibration is \( \epsilon_i \) and the
calibration interval length between the ith and the \( i + 1 \)th
calibrations is \( d_i \). The next calibration interval \( d_{i+1} \) in
FLIGHT can be predicted as:

\[
    d_{i+1} = d_i \times \frac{u}{|\epsilon_{i+1}|}. \tag{10}
\]

Initially, \( d_0 \) is set to be 20 min. Eq. (10) states that if the
drift rapidly accumulates, the calibration interval should
be short such that the drift can be corrected in time; vise
versa. In Section 5, we will investigate the impact of \( u \).

### 4.4 Upgraded to time synchronization

Clock calibration only guarantees a similar increasing rate of the maintained logic clock despite of different
starting times. As mentioned in Section 2.2 and [13],
[14], [16], clock calibration itself serves for a variety
of useful applications. Sometimes, people may want to
upgrade to time synchronization for a finer understanding
of the system performance in the time domain. For
instance, nurses in the healthcare networks may need to
understand timely situations of monitored patients.
System operators in wireless sensor networks may need to
record the exact time of certain events. FLIGHT can be
easily used to facilitate such an upgrading. To eliminate
the clock offset globally, we may simply adopt the
FTSP protocol [11]. With the FLIGHT calibration, we do
not need to run the full synchronization protocol with
heavy intercommunications between nodes. Instead, we
only need to cancel the initial time difference with one
communication round. We note that the communication
overhead and energy consumption to maintain an absolu-
tate clock value can be dramatically reduced when clocks
of nodes are already precisely calibrated with respect to
a common time reference.
5 PERFORMANCE EVALUATION

In this section, we evaluate the system performance of FLIGHT through extensive experiments.

5.1 Filter configuration

In Figure 10, we evaluate the impact of the order of the filter by varying it from 1 to 7. Figure 10(a) shows that when \( m = 1 \), the period generation component leads to the largest detection error. From statistics, we observe that the average error reaches as high as 323\( \mu s \). As we increase \( m \), errors of generated periods reduce dramatically. From Figure 10(a), we can also notice that if we increase \( m \) after 5, the error reduction is slight, implying that the order of the filter can be kept relatively low without compromising the achieved period accuracy. In Figure 10(b), we further examine the processing delay to filter one sample respect to different filter orders. As what we expect, the filtering delay becomes linearly increased when \( m \) increases as depicted in Figure 10(b). Such a processing delay essentially limits the maximum sampling rate that can be used for each specific \( m \); otherwise, the filtering and sampling operations cannot be parallelized. To facilitate the sampling rate selection for the practical development, we plot the maximum sampling rates allowed for each \( m \) in principle (i.e., theoretical maximum in Figure 10(c). Since feasible frequencies in practice are not continuous, in Figure 10(c), we plot the maximum frequency that can be adopted for each \( m \) in the TelosB platform as an example. Based on the results in the figure, we find that the pair of \( m = 6 \) and \( f_s = 7.06 KHz \) can produce both a small period detection error and a sufficiently high sampling rate.

In Section 4.2.2, we claim that the filtering computation should be completed within two consecutive samplings; otherwise, the inaccurately detected periods may incur serious logic time errors. To validate such an argument, we conduct an experiment using two TelosB motes. In this experiment, \( m = 6 \) and the sampling rate changes from 3.72 KHz to 12.42 KHz. After the initial calibration, we examine their logic time error in 10, 20, and 30 minutes. From Figure 11, we can easily observe that when \( f_s \) is greater than 7.06 KHz, the error increases dramatically. On the other hand, due to the extra computation burden from the period delimiter searching and the interruptions of the MCP to other tasks, the 7.06 KHz sampling rate may not always provide sufficient safe guarding region to parallel the sampling and computation. As a result, the synchronization accuracy might be impacted. In our experiment, we use a smaller frequency value 3.72 KHz that offers adequate safe guarding region and reliably provides a small logic time error. We use the 3.72 KHz sampling rate in the following experiments.

5.2 Logic time accuracy

In this section, we examine the logic time differences of different nodes in both static and dynamic environments.

5.2.1 Static environment

In the static environment, 12 sensor nodes are uniformly distributed in our laboratory. One beacon node is placed in the middle of the laboratory and broadcasts beacon messages to trigger each node logging its current logic time. The experiment is conducted for one week and we summarize the performance from Figures 12 to 16.

Figure 12 depicts the max and average logic time errors with respect to a randomly selected reference node. We plot one 24-hour trace clip for a clear presentation. Overall, the trace evolves following a zigzag pattern. The sudden drops of two curves are due to the logic time updating in each calibration window. From Figure 12, we can observe that on average, different clocks have been tightly synchronized. From statistics, we find that the average error keeps less than 600\( \mu s \) all the time and it is smaller than 200\( \mu s \) for over 80% of time. The maximum logic time error is also well controlled in the experiment. Statistics show that the maximum error is always smaller than 950\( \mu s \) and it is less than 350\( \mu s \) most time. Figure 12 indicates that clocks can be highly calibrated by FLIGHT.

To further understand the logic time accuracy, we examine three typical node pairs and depict their pairwise errors. In particular, the first pair of nodes are physically close to each other and they are synchronized to the same lamp. For over 80% of time, the mutual logic time error is limited by 300\( \mu s \) and the maximum error does not exceed 850\( \mu s \). The second pair is physically
apart from each other and they are synchronized to different lamps. Their mutual logic time error is still smaller than 450μs for over 80% of time. Meanwhile, the maximum error is always smaller than 900μs. The last pair of nodes might be temporarily blocked from the lamp by students or staffs in the laboratory during the experiment. However, we do not observe a significant performance deterioration and the error is below 650μs for 80% of time. In the worst case, their mutual logic time error is 960μs.

In Figure 14, we evaluate the adaptive calibration interval scheme compared with the deterministic interval setting. We choose five different error controlling factors to be 5, 10, 15, 25, and 30 native clock ticks and each native clock tick corresponds to 30.515μs. For each factor, the experiment lasts 5 hours. When the experiment terminates, we calculate the average length of the calibration interval to be 8, 15, 24, 35 and 52min, respectively. Then, we repeat the experiment for the same duration by using the deterministic calibration interval policy with the calculated interval length. In Figure 14, we plot the average, maximum, and minimum logic time errors observed in the experiment. From the figure, we find that the deterministic policy generally incur a larger error than the adaptive policy. In order to control the average error below 500μs as [14], [16], we choose 25 as the default value of \( u \) since such a setting can achieve the accuracy requirement and reduce the number of calibrations at the same time.

In Figure 15, we examine the impact of the light intensity on the logic time consistence. In this experiment, we open one lamp array in the rear of our laboratory and switch off all other lamps. Then, we place sensor nodes in a line covering both light region and dark region. In Figure 15, the x-axis represents the approximate distance of one node to the rear of the laboratory. We first plot the received light intensity in Figure 15. As the node becomes far away from the rear region, the detected light intensity drops. From Figure 15, we can observe that when the light intensity is higher than 25mV, logic times are accurately maintained, e.g., the logic time errors are smaller than 600μs after 30 minutes. Only after the light intensity drops below 25mV, the logic time error reaches 780μs. However, such a performance is still acceptable in many systems with the 1ms error bound [16]. As a matter of fact, in most indoor environments, the node can normally observe 50mV above light intensity. Therefore, one lamp can cover a large-scale field such that fluorescent lamps can be sparingly used in FLIGHT.

Finally, we examine the impact of the interference from other light sources. We first mix the fluorescent light with the sunlight, which commonly occurs when the node is deployed close to the window. The sunlight is a direct signal. We observe that the combined reading of the node consists of a 800mV direct component and a 90mV alternating component, and find that the periodical pattern from fluorescent lighting can still be accurately detected. The result shows that up to 80% of time, the logic time error is less than 600μs. In addition, we also mix the fluorescent light with the LED signal from a smart phone, which is the most widely existing noise for FLIGHT in the indoor environment. Although the generated light from LED is relative stable, due to the slight shaking of the smart phone, the amplitude of the combined signal varies, and the amplitude of the LED signal is greater than that of the fluorescent light. Similar to Figure 5, FLIGHT can still capture the frequency component close to 100Hz and accurately detect the lighting period delimiters. From statistics, we observe that the logic time is still accurate. Figure 16 shows that the error is controlled within 900μs and in most cases the error is less than 610μs. Finally, we mix the fluorescent light with the filament light that is another common noise for FLIGHT. In this scenario, the logic time is also accurate according to Figure 16. Therefore, we believe that FLIGHT is robust to external interferences from other light sources during clock calibration.

5.2.2 Dynamic environment
In this subsection, we conduct several trails of experiments to evaluate FLIGHT in dynamic environment. In the first experiment, two sensor nodes (A and B) are attached to the gates of the laboratory. Notice that only the gate with sensor node A can be open. Both of the two nodes can synchronize their clocks with the same lamp. To avoid disturbing the entrance of students to the laboratory, node A transmits its recorded logic times through wireless communications. This experiment lasts
We configure four schemes with consistent settings (with comparable timing accuracy) and report the results in Figure 20. We evaluate the energy consumptions of FLIGHT, ROCS, and WizSync, by varying the calibration interval from 10 minutes to 30 minutes. From Figure 20, we can see that the communication-based protocol indeed incurs a high-energy consumption. Compared to FLIGHT, ROCS, and WizSync, the power consumption of FTSP is much higher even when we set a much larger calibration interval. As we can see from Figure 20, the energy consumption of ROCS and WizSync is similar with the same calibration interval setting. Due to the uncertainty of the Wi-Fi beacon period, the calibration interval of WizSync is usually configured to be 10 minutes in practice and the corresponding power consumption is around 50 μW. The calibration interval of FLIGHT and ROCS can be set around 30 minutes, so their energy efficiencies are around 40 times and 6 times higher than WizSync, respectively. Since sampling the light sensor in FLIGHT consumes much less energy than operating the FM receiver module in ROCS, FLIGHT can achieve higher energy efficiency.

### 6. FLIGHT for Context Recognition

So far, we have introduced how fluorescent lighting is used to maintain a common notion of time in the network. As a promising extension to leverage its periodic property, we find that the periodical pattern obtained from FLIGHT can be viewed as an indoor context indicator, based on which the on/off states of a variety of location-based services can be controlled automatically. For example, before turning on GPS, one may first check whether it is outside a building. Before searching for...
the access points of WiFi, one may check whether it is inside or near buildings. In this section, we leverage the periodical pattern and the intensity of fluorescent lighting to identify the indoor/outdoor context for a variety of embedded devices, e.g., on-board GPS modules, embedded computer systems, mobile sensor motes, etc.

Figure 21 illustrates the basic principle of our design. First, the light intensities in the indoor and outdoor environments have significant differences. For example, the outdoor light intensity is normally greater than 400mV in the daytime. At night, however, its light intensity is smaller than 15mV (even less than the indoor light intensity). In addition, in the indoor environment, the probability to successfully detect the periodical pattern of fluorescent lighting is quite high. On the contrary, the periodic pattern detection probability in the outdoor scene approaches to zero. During the brief transition between the indoor and outdoor environments, the feature of the detected light is exhibited between two extremes.

**Approach:** within a $w$-second window, FLIGHT samples the light sensor and counts the number of detected light periods in the window. We denote $n$ to be the period counts and $\bar{n}$ to be the maximum number of periods that can be detected within the window. If the ambient environment is full of fluorescent lighting, $n$ is close to $\bar{n}$. $n$ can be slightly smaller than $\bar{n}$ as the starting point of a sampling window may not be perfectly aligned with the delimiter of a light period. On the other hand, if parts of the readings are obtained from a transition range between the indoor and outdoor environments or a complete outdoor environment, the ratio $r = \min(n, \bar{n})/\max(n, \bar{n})$ can be much smaller than 1, as the period extraction module may fail to output certain (even all) delimiters in those scenarios.

For better energy efficiency, the device needs not to sample the light sensor all the time. Instead, the sampling is in a duty-cycled manner. We configure the window size to be one second and the device samples the light sensor every two seconds. As people’s normal moving pace is about 1 m/s, two consecutive sampling sites are approximately 2 meters away, which preserves sufficient fidelity. With such a setting, the working power of our context recognition solution is 1.798mW merely. If the device is equipped with accelerometers, the duty-cycled sampling is performed only when the mobility is detected to further reduce the energy consumption.

The detection procedure is detailed in Figure 22. We first use the average light intensity level ($l$) to classify two cases. When the system operates, we assume the light sensor is available and has a valid reading.

- When $l$ is greater than a threshold $l_u$, the device possibly stays in the outdoor environment. In this scenario, the range of ratio $r = \min(n, \bar{n})/\max(n, \bar{n})$ is between 0 and 1. If the current ratio $r$ is sufficiently small, the confidence for the device indeed being outdoor is high, and we denote the confidence level as $c = 1 - r$. The confidence about the device being outdoor is low if a large $r$ is observed.
- When $l \leq l_u$, the device reads to the on-board time information. When the timer indicates the daytime or the ratio $r$ is greater than a threshold $r_u$, we have high confidence about the device being indoor. The confidence setting is given in Figure 22. In case it is at night and $r \leq r_u$, the device refers to the light intensity again. If $l < l_d$, we have high confidence that the device is outdoor, i.e., $c = 1$. Otherwise, the confidence is relatively low, i.e., $c = 1 - r$.

To properly set the thresholds $l_u$, $l_d$, and $r_u$ used in the design, we collect indoor/outdoor light intensity traces for an empirical investigation. We find that on a sunny day, the light intensity is usually above 600mV. Even on a cloudy or rainy day, the light intensity is above 500mV. Differently, indoor light intensity is relatively stable that is around 170mV. We thus set $l_u$ to be 400mV as the default value to reserve sufficient safety margin. In addition, the reading from light sensors at night is close to zero in the outdoor. If a device senses light from
street lamps or buildings, the light intensity is usually smaller than 75mV. We set $l_i$ to be 15mV (to tolerate certain hardware jitter) as the default value to identify the scenario when the node is completely outdoor at night. On the other hand, in the indoor environments, the quality of the detected periodic patterns, measured by $r$, is usually close to 100%. We configure $r_u$ to be 95% to reserve a 5% safety margin.

In Figure 22, one point worth noting is that the detection result for “outdoor with low confidence” does not imply the device probably being indoor. It only states the harvested evidence is not strong enough for a device to conclude its ambient context as “outdoor” though the device knows it is not likely being indoor. The reason is due to the transition range between the indoor and outdoor environments. We find that identifying the transition scene is sometimes useful. For instance, in the transition environment, GPS should not be switched on as the GPS receiver may not observe enough satellites at this time. In contrast, the WiFi module can be turned on since the device is already in the vicinity of a building. Thus, the detection confidence is used as one input for upper-layer applications.

**Evaluation:** we evaluate the performance of our context recognition approach in Figure 23. Four students participate the experiment and each of them randomly selects 25 indoor and 25 outdoor sites in the campus. The experiment lasts for 5 days with different weather conditions and include different periods of a day, e.g., daytime, night, sunrise, and sunset. The results show that in the outdoor environment, the device can accurately detect its ambient context. The accuracy is as high as 95%. In the indoor environment, we find that other type of light sources may cause the detection error. Moreover, when the device is close to the door and the door is just open, our approach might classify the device to be outdoor with low confidence. According to the statistics, the indoor detection accuracy is 90%.

### 7 Related Work

Most existing works for achieving common time notion in the network rely on wireless communications. RBS [9] eliminated the sender-side delay for synchronization. TPSN [10] further canceled out the propagation delay. By using the MAC-layer stamping technique, FTSP [11] largely increases the synchronization accuracy. However, the authors in [12] find that errors among different clocks exponentially increase with the network diameter. [22] proposes a fast flooding scheme and [20] studies the synchronization accuracy in low-duty-cycle sensor networks. [23] estimates clock uncertainty for duty-cycled sensor networks. On the other hand, some other works also focus on addressing the clock uncertainty and reducing the time synchronization cost. ACES [19] suggested to track skew by using Kalman filter and ODS [7] introduces the on-demand accuracy synchronization. Both [24] and [25] explore the temperature compensated scheme to mitigate the clock skew. In [20] and [21], authors introduce to maintain a common time by using two clocks on each individual node with different accuracies. Communication-based protocols are easy to implement but with high energy consumption and overhead.

Recently, several emerging studies exploit the external signal source with a stable period for clock calibration and synchronization. The majority of those solutions utilize radios for the clock calibration at the expense of higher power consumption [14], [26]. Although clock calibration can be performed periodically, the energy consumption for each calibration could not be reduced and the accumulated power draining for time synchronization is still high. [15] designs passive radio receivers for synchronizing nodes to radio stations. In [16], authors introduce to synchronize clocks to Wi-Fi beacons without the extra hardware support. Such a global reference, however, may not be stable enough due to channel contention and collisions. In [13], the authors propose to use power lines for clock calibration. However, due to dramatically decay, the periodical signals can only be detected in the vicinity of power lines. Extra hardware is required as well in [13]. On the contrary, FLIGHT is not constrained by those limitations and FLIGHT can precisely calibrate clocks in an energy-efficient manner without any specific hardware.

Initial efforts on the context recognition have been made [18], [18], however, focuses on the design for smart phones using expensive sensors, which may prohibit its usage for low-end smart phones and embedded devices. Differently, we propose to solely utilize the periodical pattern and the intensity of fluorescent lighting so that a lightweight context service can be achieved.

### 8 Conclusion

In this paper, we develop a new clock synchronization approach called FLIGHT, which leverages the fact that the light intensity from fluorescent lamps varies with a stable period. FLIGHT does not require any extra hardware and radio operations. By sampling light sensor or camera, FLIGHT can intelligently extract periods for the clock calibration and retain a common notion of time in the system. We give in-depth analysis on various practical issues to ensure the calibration accuracy. We implement FLIGHT in TelosB motes and evaluate its performance using a 12-node test-bed under both static and mobile settings. We further leverage the observation from FLIGHT for context recognition, which utilizes the
periodical pattern and the intensity of fluorescent lighting to distinguish the indoor and outdoor environments.
